NEBRASKA SURVEY OF BIOMASS:
AVAILABILITY AND ENERGY UTILIZATION POTENTIAL

EXECUTIVE SUMMARY

1.0 Introduction

The State of Nebraska is participating in the Western Regional Biomass Energy Program (WRBEP), one of five U.S. Department of Energy Regional Biomass Energy Programs. The purpose of these programs is to stimulate private sector use of biomass energy technologies and to encourage technology transfer efforts.

This project has analyzed the potential for conversion of Nebraska's biomass resources into energy resources on a county-by-county basis. The analysis includes a summary of the total resource produced, the amount of the biomass resource that is available for energy conversion, and the amount of energy that could be produced in the form of heat, liquid fuel or gaseous fuel. Alternative conversion technologies will be examined as appropriate for the resource.

2.0 Summary of Methodology

Production data in the form of acres of forests and crop land in use and the average productivity for this land was assembled using the 1987 Nebraska Agricultural Statistics as the base. The crop lands of interest for estimating harvestable crop residues are the Soil Conservation Service Class I, II, and III lands, so the distribution of these lands was also determined.

Crop production by land class was estimated for both irrigated and non-irrigated farming using the assumption that the most valuable crops will be preferentially planted on the best land. The crops considered in this inventory are corn, soybeans, sorghum, wheat, alfalfa, barley, oats, and sugar beets.

Crop residues available for use as an energy resource were estimated using accepted ratios describing residue weight per product weight and by taking into account the conservation requirements applicable to the land class on which the crop was grown. Residues on Class I lands can be harvested completely, while 80 percent of the residues from Class II lands can be harvested. Only 50 percent of residues from Class III lands can be taken. No residue harvest is permitted from Classes IV - VIII. In addition, a residue harvest efficiency of 70 percent was applied to all residues.

Forest products were inventoried using the 1983 Forest Products Inventory. The species considered are cottonwood, bur oak, green ash and ponderosa pine. Manure resources from feedlots were also estimated.

Each residue resource was evaluated as a potential energy source for production of synthetic natural gas using anaerobic digestion, electricity by direct combustion, ethanol via fermentation, and methanol by gasification and synthesis. Corn and sorghum were also considered as resources for fermentation ethanol, after allowing for animal feeding requirements to be met.

3.0 Summary of Findings

3.1 Land Resources and Utilization

The majority of the commodity crops grown in Nebraska appear to be grown on Class I, II, and III lands. An analysis of the trends in participation in the Conservation Reserve Program (CRP) suggests that the higher quality land is being farmed and the poorer lands are in the reserve. The conclusion drawn from this is that the CRP lands are not likely to be useful as an additional resource for production of energy crops or harvestable residues.

Similarly, the forest resources of the state are shrinking in terms of area, but stable or increasing slightly in terms of net volume of growing trees. There is a high utilization of the oak and ash resources for fuel wood now. The cottonwood and ponderosa pine resources are used as saw logs, veneer and posts, with relatively little used as fuel. The forestry resource does not appear to be easily expanded to accommodate energy production beyond the current level of use. In fact, there is a likelihood that the oak fuel wood resource is declining.

3.2 Resources Not Useful for Energy Conversion

Several of the crops surveyed are considered to be not suitable for contributing as biomass energy resources. Alfalfa, barley, oats, and soybeans have higher value uses than energy and were not considered as resources. The residues of oats and soybeans were also not considered. Sugar beets can be used to produce ethanol, but there is not sufficient production to support the minimum economically viable plant, 20,000,000 gallons

per year. Wheat combined with harvestable residues is available in sufficient quantities to support a 20,000,000 gallon per year plant only in two counties. Therefore, wheat was not considered as a viable resource for ethanol.

The feedlot wastes in the state are insufficient in quantity to support either anaerobic digestion for methane or gasification facilities. In fact, anaerobic digestion of feedlot wastes and of crop residues for the production of synthetic natural gas is not economically feasible for the state. The distribution of methane production potential for the state is shown in Figure 1.

3.3. Ethanol Production

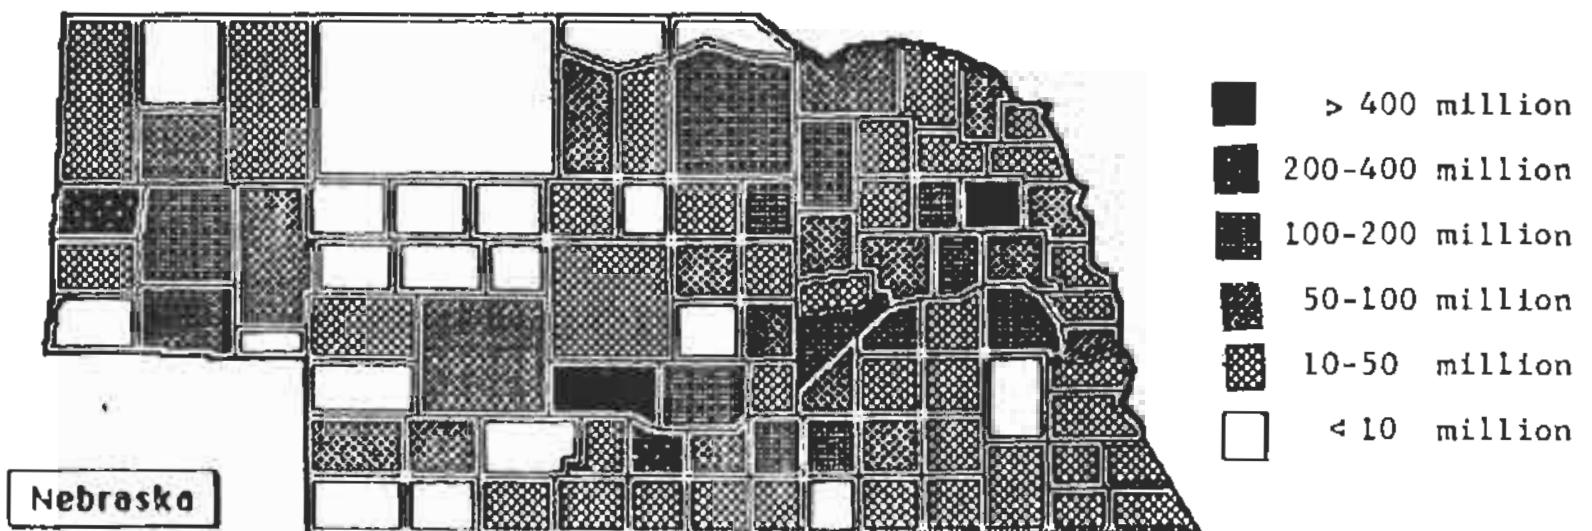

There is sufficient corn production, after animal feed requirements have been met, that 34 counties could support 20,000,000+ gallon per year (20 MM+ gpy) plants and 16 counties can support 40 MM+ gpy operations. When harvestable residues are included for corn, then 45 counties can operate at the 20 MM+ gpy level and 22 counties could support 40 MM+ gpy operations. Currently approximately 10,000,000 gallons per year of ethanol are produced from corn in the state.

Sorghum is much less attractive as a basis for ethanol production. Seven counties can support a 20 MM+ gpy plant.

The fact that usually there are several significant crops grown in a county expands the locally available resource considerably. When considering potential ethanol from all sources, using grain fermentation and cellulose conversion of residues, the economically viable potential production for the state is impressive. Fifty-seven counties can support 20 MM+ gpy

Figure 1

Total Methane Potential from Residues and Manure
(Million Cubic Feet Per Year, By County)

plants and 22 counties could support operations at 50 MM+ gpy. This means that out of the 2100 million gallons of gasoline used in the state annually, 1560 million gallons could be ethanol produced in economically viable sized plants. The total potential ethanol production using all resources is 2940 million gallons. The distribution of potential ethanol production from all sources is shown in Figure 2.

3.4. Methanol Production

The residue materials can also be converted to methanol using a process of gasification. The gasification scheme converts the residues into a mixture of carbon monoxide and hydrogen, and then to methanol. Approximately 0.365 pounds of methanol are possible from each pound of residue.

The total methanol capability for the state is 1908 million gallons. There are 18 counties that can support the minimum economically viable plant, 30 MM gpy, and 8 counties can support a 50 MM+ gpy operation. The approximate economically producible methanol capacity for the state is 908 MM gpy. The distribution of potential methanol production from residues is shown in Figure 3.

The total fuel yield per pound of residue is higher for methanol than for ethanol for all of the residues considered, except for sorghum. The sorghum residues actually produce more ethanol per pound because of the natural sugars present in the stalks.

3.5. Direct Combustion of Residues

Another alternative use for crop residues is direct

Figure 2
Total Ethanol Potential from Grain and Residues
(Million Gallons Per Year, By County)

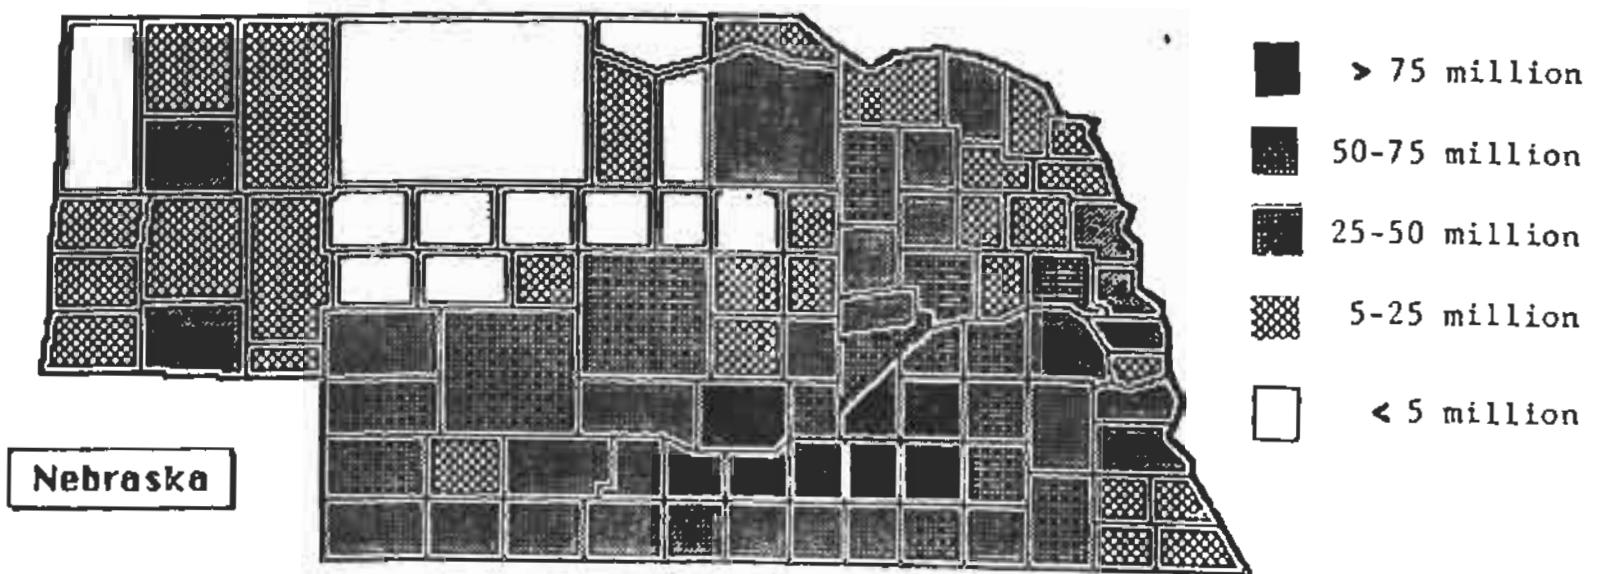

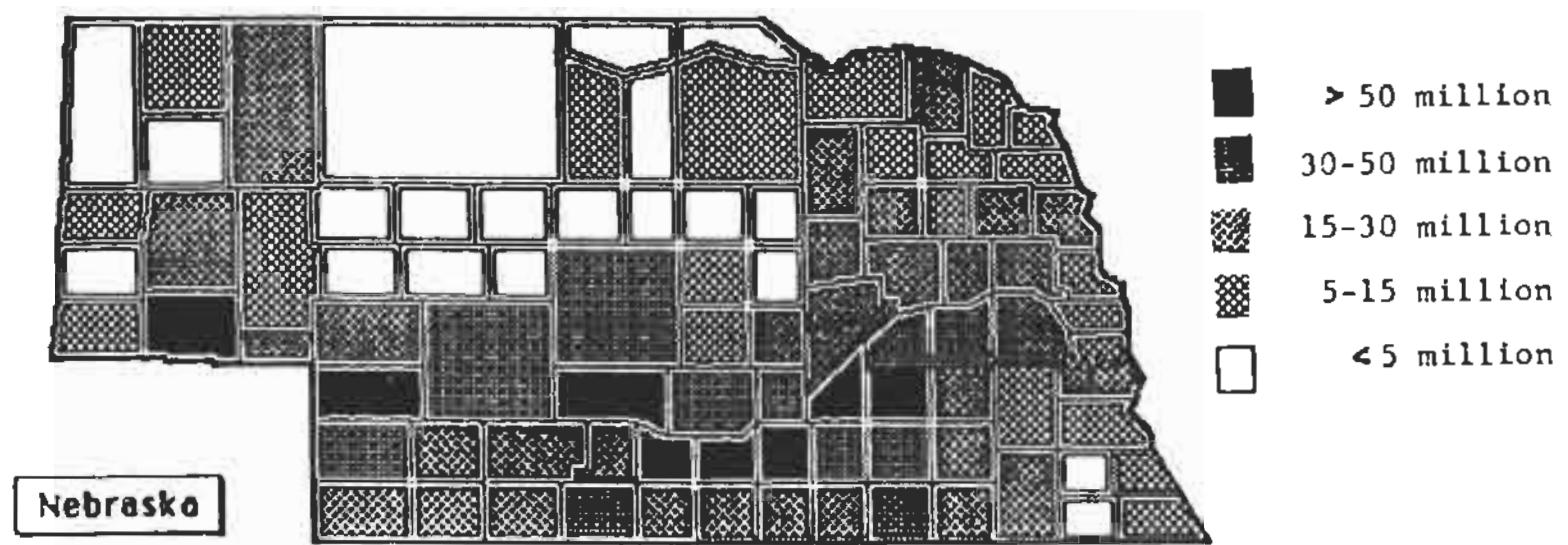

Figure 3
Total Methanol Potential from Residues
(Million Gallons Per Year, By County)

combustion. The energy potential for combustion of residues was evaluated on the basis of replacing fossil fuels with residues in electrical power generation. The major problem associated with this use is the necessity of densification and transportation of the residues to the power generation site. The total harvestable residues in the state represent a potential 64,185 million kilowatt hours, compared with 16,763 million kilowatt hours actually used. Eighty-three of the 93 counties can meet all of their electrical needs by burning harvestable residues. The distribution of potential electrical production from combustion of residues is shown in Figure 4.

4.0 Summary

Nebraska has the potential to be relatively energy self-sufficient in liquid fuels and electrical power. This goal of sufficiency must be tested for economic viability before it is considered as a policy goal. The use of harvestable residues for a combination of methanol synthesis and electrical power generation appears to be highly attractive. The production of ethanol from excess corn, sorghum residues, and some contribution from sugar beets and other grains also is attractive. Feedlot wastes are not in sufficient quantity and concentration to have an impact of energy resources, unless the conversion is a part of a waste treatment strategy at a local scale. The forestry resources must be considered to be fully utilized now. Finally, it appears that acreage currently enrolled in the Conservation Reserve Program (CRP) will generally not be suitable for producing residue resources for energy production.

NEBRASKA SURVEY OF BIOMASS:

AVAILABILITY AND ENERGY POTENTIAL

1.0 Introduction

The State of Nebraska is participating in the Western Regional Biomass Energy Program (WRBEP), one of five U.S. Department of Energy Regional Biomass Energy Programs. The purpose of these programs is to stimulate private sector use of biomass energy technologies and to encourage technology transfer efforts.

This project has analyzed the potential for conversion of Nebraska's biomass resources into energy resources on a county-by-county basis. The analysis includes a summary of the total resource produced, the amount of the biomass resource that is available for energy conversion, and the amount of energy that could be produced in the form of heat, liquid fuel or gaseous fuel. Alternative conversion technologies will be examined as appropriate for the resource.

2.0 Agricultural Data

The estimates of crops and residues available for conversion to various forms of energy are based upon the 1987 crop year. Gross tonnages of row crop and small grain residues were determined for all 93 counties in the state of Nebraska. The specific objective of the study was, however, to determine the net tonnages of the several biomass resources actually available after accounting for competing demands. Primary alternative demands for crop residues are : 1) conservation compliance

requirements of the Agricultural Stabilization and Conservation Service (ASCS), 2) livestock forage, and 3) individual preferences for erosion control and cropping systems.

Additional sources of biomass energy are grains and livestock manures. Cattle and hog feedlot manure recoverable and the grain surplus (deficit) were calculated on a county basis. In specific, the county grain surplus (deficit) is equal to the county corn production, less the livestock feeding requirement. This approach does not recognize the contribution of other grains such as milo and oats to livestock feeding, nor does it recognize the simultaneous flow of county grains to the food, industrial, seed, alcohol, or export sectors.

While not generally perceived as a timber producing state, Nebraska has commercially significant timber production in several localities. The acres devoted to commercial timber and the commercial production of the four most important species, cottonwood, bur oak, green ash, and ponderosa pine are presented in detail in Table 1. Use of forest products is divided between saw logs, including a small usage for veneer and poles, and fuel wood. A census of Nebraska sawmills by capacity and county is also included.

Crop acres and yields are reported in the 1987 Nebraska Agricultural Statistics. The data are available in the Nebraska Natural Resource Commission's (NNRC) Natural Resources Data Bank. County-level Land Capability Classes are also available from the NNRC. Land Capability Class data were collected by the Soil Conservation Service (SCS) and reported in the 1982 National

Resources Inventory (NRI). The 1987 Census of Agriculture (Nebraska: State and County Data) compiles fed livestock marketings and Conservation Reserve Program (CRP) acreage information. Feedlot capacities were obtained from the Nebraska Department of Environmental Control and the Nebraska Agricultural Statistics. Forestry data was summarized from the 1983 inventory done by Raile (1986).

3.0 Crop Residue Calculations

The usable crop residues were estimated using the residue yield factors proposed by Larson, et al. (1978) which give the relationship between crop residue weight and grain yield weight (fodder to grain ratio). The fodder to grain ratio and the pounds of grain per bushel for different grains is given in Table 1. These values are similar to those given by SRI (1979) as modified to account for needed field cover to maintain field protection (ORNL, 1982). The results are presented in a form similar to the Illinois biomass resource survey completed by Argonne National Laboratory (1980). The first step in calculating net available biomass was to determine the land capability class for each planted acre of grain. Eight land capability classes have been established by the SCS. However, residues may only be removed from classes I, II, and III lands in accordance with ASCS land conservation requirements.

Class I lands can be used for continuous crop production. They have slopes of less than 2%. All crop residues may potentially be removed from Class I land. Class II land has slopes of 2 - 5%, and 20 % of the crop residue must be maintained

on the surface of the soil to maintain soil conservation protective requirements. Class III soils have severe cropping limitations, with slopes of between 6 and 11%. At least 50% groundcover must be maintained. Approximately ten percent of Class III land is farmed under no-till operations, so crop residues are available for harvest. However, ninety percent of Class III land is farmed with conventional tillage practices, which incorporate the residue. Since incorporated residue is unharvestable after it is incorporated, only 10% of Class III land has harvestable residue, of which only 50% can be removed. Crop residues cannot be removed from Land Capability Classes IV - VIII because of severe limitations such as steep slopes requiring ground cover, stones, swamps, etc.

In summary, harvestable residue is a function of both the conservation requirements (land class) and harvest efficiency. Typically available residues can be harvested with a 70% efficiency. This means that the amount of residues actually available from Class I land is 70% of the theoretical residue yield (fodder to grain ratio). Similarly, only 56% of the residues from Class II lands are available and 3.5% of the residues from Class III lands can be used.

4.0 Estimating Crop Acres by Land Class

Biomass can be harvested from Class I, II, and III land, but the actual amount of available biomass is also directly related to the specific crops planted on each land class. An allocation process had to be established which would estimate the specific crop acres and their land capability classes. The NRI reports

non-irrigated and irrigated land capability classes. The NRC Data Bank reports non-irrigated and irrigated crop acres and yields. County level data are available for each data set.

The allocation process is an estimate, since crop acres are not reported by land capability class. However, several basic assumptions were made. First, the crop that yielded the highest net return per acre was allocated to the most productive land. Any remaining land in the same class would be allocated to the next most valuable crop, and so on. The crops were ranked in the order shown in Table 2. The only irrigated crops analyzed were corn, alfalfa, soybeans, and sorghum. They were allocated in the order given.

For example, assume the amount of Class I, II, and III land is 500, 1000, and 400 acres, respectively. A total of 700 acres of corn would be allocated as 500 acres in Class I and 200 acres in Class II. The remaining Class II acres would be allocated to the next most profitable crop until all of the land and all of the crops are allocated.

This allocation process is an estimate of the actual crop acreages among the different land capability classes. The actual allocation will differ for individual farmers and among Crop Reporting Districts.

The methodology used here explicitly allows for the fact the not all residues can be harvested (harvest efficiency). Also, this method recognizes the fact that not all residues should be harvested. The result is a set of estimates that is inherently conservative in terms of total potential resource, but sustainable for long term productivity.

5.0 Crop and Residue Production Data

The crop and residue production data given here are based only on crops produced on Class I, II, and III lands. For this reason the total crop production given will be somewhat lower than the actual totals reported in the 1987 Nebraska Agricultural Statistics. The estimates for energy product potential is also based on the lower figure.

The distribution of land by soil classification among Classes I, II, and III is given for the 93 counties in Table 3. The data in the table and throughout this report are arranged by county, within the several crop reporting districts. This arrangement makes it easier to see the regional/geographical differences among the resources.

The Conservation Reserve Program (CRP) has the intent of setting aside up to 25 percent of the acreage classified as farms in a county from active crop production. Table 4 summarizes the acreages designated as farms, total Class I, II and III acres and CRP set aside acres. The information is current as of the ninth enrollment in February, 1990. Also shown is the percentage Class I, II and III land and percentage CRP land on a county by county basis.

It is evident from Table 4 that counties with relatively little higher quality land tend to participate more in the Conservation Reserve Program. There are a few counties, particularly in the southeast, that appear to have some of the Class I, II, or III land involved in the CRP set aside. The disparity between farm acres and Class I, II, III acres for

Frontier county may be an indicator of land not in production or changes in land use between the census year, 1987, and the CRP census, 1990.

The acres of the irrigated crops: corn, sorghum, soybeans, and alfalfa planted on Class I, II, and III lands are summarized in Table 5. The non-irrigated crops: corn, sorghum, wheat, soybeans, alfalfa, oats, beets and barley are tabulated in Tables 6 and 7. Table 8 shows yields for irrigated crops, while Tables 9 and 10 give the same information for the non-irrigated crops.

Total residues harvestable for both irrigated and non-irrigated crops are summarized in Table 11. The figures given represent 70% of the residues from Class I lands, 56% of the Class II residues and 3.5% of the Class III materials. The total amount of feedlot manure is based on the data and assumptions described in the next section.

6.0 Livestock Manure Utilization

Large Nebraska feedlots produce tons of manure which, if not properly disposed of, are potential sources of serious pollution. The data for estimating the quantity of the manure resource in the state was collected from the 1987 Nebraska Census of Agriculture, the Nebraska Department of Environmental Control and the Nebraska Agricultural Statistics.

Proprietary information has not been disclosed. If four or more feedlots are in operation in a county and if less than 60% of total county capacity was produced in any one feedlot, then the more accurate data from the Nebraska Agricultural Statistics (NAS) were reported. The data from the Nebraska Department of

Environmental Control, which is public information, was reported if fewer than four feedlots operated, or if 60% of the county total was produced in one feedlot. In order to assure confidentiality, only the aggregate figures for cattle and hog manure are reported in this document on a county basis.

The expected manure output of the 2000-head plus feedlots is based on the expected number of cattle on feed. The number of cattle on feed at a given time is estimated to be 70% of the feedlot capacity. The amount of manure actually available is affected by feed consumption, climate, cattle densities, and the manure removal technique.

Cattle consuming 20 pounds of feed a day will pass about 5 pounds of manure per day. Typically, only 50% of the deposited manure is recoverable. In order to estimate the total manure resource, it was assumed that cattle are fed about 350 days per year, with the other 15 days for manure removal, marketings, and cattle replacement.

The December hogs and pigs inventory in 1000-head plus lots is reported in the 1987 Census of Agriculture. The expected annual average inventory is assumed to be the same as the December inventory, although seasonality of production is present. Manure is assumed to be produced 350 days per year.

The **Livestock Waste Facilities Handbook** indicates that a finishing pig passes slightly less than one pound of dry matter per day. However, as in the case of cattle manure, only 50% recovery is anticipated. The efficacy of recovering hog and pig manure is questionable. Small operators can disperse manure over

their farmland, thus avoiding the pollution that results from large concentrations of manure. Similarly, transporting small lots of manure to a conversion facility is an expensive alternative.

7.0 Forestry Products and Utilization

Four species, cottonwood, white oak, green ash, and ponderosa pine account for more than 80 percent of the forestry products produced in the State of Nebraska. The net volume of the growing stock for these four species is summarized in Table 12. The growing stock is representative of the potential supply, rather than annual production.

Annual production and use data for cottonwood and oak are summarized in Table 13 and data for green ash and ponderosa pine are given in Table 14. County-by-county data are not available. The figures in Tables 13 and 14 were estimated using the statewide annual production of saw logs, veneer and poles in 1980 as an aggregate for saw logs and taking the ratio of the production volume to the net volume of growing stock for the species and multiplying this ratio by the net volume of growing stock in the county. The county-by-county production of fuel wood was computed similarly.

It is important to note that there already is a significant use of timber as fuel wood in Nebraska. Seventy-seven percent by volume of the timber used in Nebraska in 1980 was for fuel wood. The oak and ash grown is essentially all used as fuel wood. The cottonwood and ponderosa pine are mostly used as saw logs.

There is little likelihood of significant expansion of the energy use from forestry products in the state. As seen in Table 15, there are few sawmills of sufficient size to collect sawdust and bark for energy use. The rate of ash fuelwood use allows for a 15 year regrowth period while that for oak is only 8.5 years (net volume growing stock/annual use as fuelwood). It appears that oak may be used faster than it can be replaced.

The Nebraska forest inventory (Raile, 1986) showed a substantial drop in forested acres between 1955 and 1983, but the volume of growing stock for softwoods doubled over the period and the volume of hardwoods was essentially constant. The changes indicate more intensive silviculture of softwoods in the Northwest District and (probably) better silviculture practice for hardwoods throughout the state. There appears to be little opportunity for expansion of forestry and there continues to be some pressures to convert forested lands into crop agriculture.

8.0 Energy Conversion Technologies

The primary categories of biomass energy utilization technologies are:

- a) Direct firing for heat
- b) Gasification
 - 1) Anaerobic digestion to produce methane
 - 2) Producer gas generation for low BTU gas
 - 3) Thermochemical conversion to synthesis gas for direct firing or production of other fuels (methane, methanol, gasoline)
 - 4) Thermochemical liquefaction to produce synthetic crude oil
- c) Fermentation for production of ethanol
 - 1) Starch/sugar fermentation
 - 2) Xylose fermentation
 - 3) Cellulose conversion to glucose

The basic process descriptions and energy yields for these technologies have been summarized by a number of authors (SRI, 1980; Lowenstein, 1985). The energy yield for the best presently available technology under each of the categories listed above will be used to compute the energy available from each resource.

In many cases the same resource can be used in several different conversion processes. For example, corn kernels can be burned, fermented to ethanol, gasified anaerobically or thermochemically or made into synthetic crude oil by liquefaction. The energy yield and final product yield (BTU's of heat, gallons of ethanol, etc.) will be calculated for options considered appropriate for the resource.

8.1 Fermentation for Ethanol Production

Ethanol may be used as a liquid transportation fuel either as pure ethanol or in a 10% mixture with gasoline (gasohol). Fermentation ethanol may be produced either from starch and/or glucose (six carbon sugar), from pentoses (five carbon sugars), or from the conversion of cellulose and hemicellulose to glucose and pentoses.

Glucose is available from sugar beets and, to some extent from sorghum residues. All grains are primary sources for starch, which can be hydrolyzed to form glucose. Utilization of glucose or starch resources is a conventional technology which is employed commercially throughout the world.

Utilization of hemicelluloses and cellulose as a fermentation substrate requires that the materials first be reduced to the component sugars before fermentation takes place.

The reduction of hemicelluloses to pentoses and some hexoses is fairly simple, but the fermentation yields are still fairly poor. Cellulose, a polymer of glucose, can be reduced to glucose either enzymatically, or by using mineral acids to hydrolyze it.

There is considerable variation in the literature with regard to the yield of ethanol from a given substrate. The values used in this work and shown in Table A represent an average of several results reported in the literature. Actual yields, particularly in the case of residue utilization, may vary considerably. The conversion factors used for residues are all based on acid hydrolysis results.

Table A
Yield Factors Used for Fermentation Ethanol Production

Corn	0.595 lit/kg
Wheat	0.41 lit/kg
Barley	0.41 lit/kg
Sorghum	0.41 lit/kg
Sugar Beet	0.63 lit/kg
Corn Residue	0.18 lit/kg
Wheat Residue	0.21 lit/kg
Barley Residue	0.13 lit/kg
Sorghum Residue	0.51 lit/kg

Soybean residues were not considered because they typically are not harvested. Alfalfa was considered to be a forage crop only and was not considered an energy resource, although it would have about the same conversion ratio as the small grain residues.

Table 16 summarizes the computation of the potential yield of ethanol from corn for the state of Nebraska. The restrictions placed on the results in the table are that only corn grown on Class I, II, and III lands is considered, and that corn must first be used to satisfy the livestock feed demand in a county before it can fulfill any other uses.

It is important to recognize that there are a number of counties that operate at a deficit with respect to corn. Also, there are a number of counties that cannot support an ethanol plant of capacity 20,000,000 gallons per year, the approximate minimum economical size facility.

The livestock feed grain utilization was calculated using data from the 1987 Nebraska Census on Agriculture, using a USDA developed procedure for estimating feed grain disappearance. Table 17 shows the annual consumption of feed grains for a number of types of animal.

Table 18 expands the potential ethanol from corn to include ethanol produced from the harvestable corn residues produced. While there appears to be a considerable ethanol potential, it is important to note that relatively few counties have enough harvestable residue to support a cellulose conversion facility larger than 10,000,000 gallons per year. Cellulose conversion is more expensive than fermenting sugars, so it is not certain that all of the capacity shown in the table can be realized.

Sugar beets are a potentially viable basis for an ethanol facility in the Northwest Reporting District, as seen in Table 19. Other grains and their residues are summarized with respect

to potential ethanol production in Tables 20, 21, and 22. The high ethanol yield from sorghum residue is particularly interesting (Table 20). There are several counties where a combined grain and residue processing facility could be appropriate.

The fundamental purpose of this study is to identify areas where biomass-based raw materials can make a significant impact on the fossil fuel requirements of the state. The annual estimated gasoline consumption for the state is compared with the potential ethanol production in Table 23. The gasoline consumption on a county-by-county basis was estimated using a summary of annual vehicle miles provided by the Nebraska Department of Roads Office and using an average performance of 16.5 miles per gallon. The estimated gasoline consumed of 835 million gallons per year compares well with the 773 million gallons reported for 1987 in the 1960 - 1987 Energy Statistics prepared by the Nebraska Energy Office. It is important to note that Nebraska is potentially self-sufficient in liquid fuels, and, in fact, is a potential exporter of fuels with no effect on the livestock industry.

The equivalency of one gallon of ethanol for one gallon of gasoline used in Table 23 requires further comment. The energy content of gasoline, ethanol, and methanol, also derivable from biomass, are different. Table B compares the three liquid fuels on the basis of energy content per gallon. However, energy content does not translate directly into fuel performance in terms of volume of fuel required per mile driven. Scheller (1979) suggests that a ratio of 1.6 gallons of crude oil per

Table B

Approximate Energy Content Per Gallon for Liquid Fuels

Gasoline	115,000	Btu/gallon
Methanol	67,000	Btu/gallon
Ethanol	87,000	Btu/gallon

gallon of ethanol is a more accurate figure to use in comparing overall fuel performance. The more modest ratio of 1.0 gallon of ethanol = 1.0 gallon of gasoline is assumed in this work.

8.2 Methanol Production from Synthesis Gas

Any biomass material can be broken into a mixture of hydrogen, carbon monoxide, carbon dioxide, light hydrocarbons, organic liquids, char and tar by the combined processes of pyrolysis and gasification. Pyrolysis is the thermal decomposition of a molecule by heat in the absence of oxygen. The gasification reactions are a set of reactions between carbon monoxide, carbon dioxide, water, and char that can be used to increase the amount of solid material that can be converted to desirable gaseous products.

The gas mixture resulting from pyrolysis and gasification is primarily carbon monoxide and hydrogen. This mixture is called synthesis gas because it is the raw material for ammonia synthesis and for methanol synthesis. The pyrolysis/gasification process is relatively insensitive to the type of biomass material being used, except that materials with a high silica content, such as rice hulls, are a problem in most gasifiers.

Typical yields from a gasification/methanol system are 0.365 pounds of methanol for each pound of biomass. This means that for most residues it is possible to make more methanol per pound than ethanol. Table 24 is a comparison of the production of ethanol and methanol from corn residues. It is apparent that the potential methanol is double the volume of the potential ethanol. A limiting factor in the assessment of methanol potential is the rule of thumb that the minimum economical size methanol facility must process 1000 dry tons per day, or about 330,000 tons per year of residues. It is evident that many counties can achieve that quantity of material with corn residues alone.

It is not always more advantageous to make methanol from the residues, however. Table 25 demonstrates that because of the relatively high sugar content in sorghum residues, it is preferable to convert them to ethanol instead of methanol.

The total methanol potential using gasification and methanol synthesis technologies with crop residues is shown in Table 26. Methanol can also be made from feedlot wastes, as summarized in Table 27. The state can be considerably more than self-sufficient in liquid fuels based on use of the residues alone, if methanol is determined to be an acceptable motor fuel. Based on energy content, one gallon of methanol is approximately equal to 0.77 gallon of ethanol or gasoline. Although it was not considered in this study, the same synthesis gas used to make methanol can be used to make synthetic gasoline. The net volumes of synthetic gasoline are somewhat smaller than the methanol yield.

8.3 Other Energy Uses for Crop Residues

Another option for gasification of crop residues and feedlot wastes is the use of anaerobic digestion to produce methane. This process has been hampered at the large commercial scale because of the large capital investment in fermentation tanks needed. However, anaerobic digestion is one of the few technologies that can be employed at a smaller scale to produce a synthetic natural gas. Manure, when digested, yields about 4.2 cubic feet of gas per pound of manure. The methane content of the gas is about 63%. Corn residue gives about 4 cubic feet of gas per pound, but the methane content is only 50%. In preparing Table 28 it was assumed that other grain residues will perform the same as corn residue. There apparently are no county-by-county data for natural gas consumption in Nebraska, but an estimate based upon household usage is given in Table 28. The total potential of 5,283 million cubic feet (methane equivalent) of synthetic natural gas is considerably less than the 1987 consumption of 91,098 million cubic feet. It appears that the impact of anaerobic digestion technologies should be minimal, except as a local utilization and/or waste treatment strategy.

All biomass materials can be burned. It was assumed that direct combustion of the crops themselves is not a strategy suitable for large scale application. However, direct combustion of residues in applications such as steam production and electrical power generation is feasible and is being used in a number of locations throughout the world.

Table 29 also shows the potential for direct combustion of

crop residues in electrical power production. Experience in Denmark suggests that there is about 80% efficiency in converting thermal energy of biomass to electrical power in commercial practice. The potential of 64,185 million kilowatt hours of electrical generating capacity using residues compares favorably with the total 1987 electrical usage in Nebraska of 16,770 million kilowatt hours. The estimated electrical power usage shown in Table 29 suggest that some counties could be self-sufficient in fuel for electrical power if the residues could be assembled and transported economically.

Summary

Nebraska has the potential to be relatively energy self-sufficient in liquid fuels and electrical power. This goal of sufficiency must be tested for economic viability before it is considered as a policy goal. The use of harvestable residues for a combination of methanol synthesis and electrical power generation appears to be highly attractive. The production of ethanol from excess corn, sorghum residues, and some contribution from sugar beets and other grains also is attractive. Feedlot wastes are not in sufficient quantity and concentration to have an impact of energy resources, unless the conversion is a part of a waste treatment strategy at a local scale.
